---

## Difference-in-differences and synthetic control

---

Prof. Bruno Lanz  
University of Neuchâtel

MSc in Applied Economics

## Where we stand

- To estimate a treatment effect with observational data, we need to deal with selection bias
- Main insight from the omitted variable bias: selection bias materializes as confounding factors which are
  1. correlated with treatment status
  2. affect the outcome of interest
- If units who benefit more from the treatment self-select into the treatment group, the regression coefficient is subject to selection bias
- Control variables: adjust the comparison between treated and non-treated units within clusters
  - Unobserved heterogeneity (e.g. ability) can be captured with fixed effects when it is constant within-cluster

# Objectives for today

- While control variables and fixed effects are useful, they do not guarantee causal identification
  - Instead approximate experimental random assignment with “quasi-experiments” or “natural experiments”
- Difference in differences: Compare before and after treatment among treated and control units
  - Exploit control units to estimate a counterfactual outcome for treated units
  - MM chapter 5, MHE chapter 5.2
- Extension for quantitative case studies: Synthetic control method
  - Construct a hypothetical unit that is observationally similar to the treated unit

# Toward difference-in-differences: simple differences

- “Natural” experiment: exploit a change that was not made explicitly to quantify the effect of the intervention
  - Key issue: what is a valid counterfactual?
- Consider a country that introduces a policy
  - We want to quantify the impact of the policy on  $Y_{it}$  for all units  $i$  observed over time  $t$  in that country
- An obvious approach is to compare the year before ( $T_{it} = 0$ ) and after ( $T_{it} = 1$ ) the change:
$$Y_{it} = \alpha^D + \beta^D T_{it} + u_{it}$$
- $\beta^D$  measures the difference in average outcome use before and after the policy is introduced

# Data for today

- Consider a country that introduces a carbon tax in time  $t^*$
- Assume we design a survey to measure energy use (or CO<sub>2</sub> emissions) and administer it to 28 firms 6 months before the tax is introduced
  - We administer the survey again 6 months after the tax is introduced
  - Our outcome variable is energy use and it is measure both before and after the intervention
- For now we assume that these are not the same firms, and we just stack the data as if this were two cross-sections
  - In our data firms in the second wave of the survey are identified with a dummy variable *after*
- We consider the log of energy use as our outcome variable

```
. gen lnenergy = ln(energy)
```

|    | country | after | energy  | lnenergy |  |  |

# Event study with multiple periods

- Problem: with just one period before and one after we cannot distinguish the impact of policy from the passage of time
  - A dummy equal to one if the policy is introduced, zero otherwise, is redundant
- Implicitly: we assume that pre-treatment observations are a good control group
  - $\hat{\beta}$  measures the impact of the policy only if we assume that there would have been no change in  $E[Y_{it}]$  absent the policy change
- If we have more than two periods (before/after): Event study analysis
  - Years 1,...,T are available and the policy starts in year  $t^*$   
$$Y_{it} = \alpha_1 + \sum_{\tau=2}^T \beta_{\tau} I_{\tau} + u_{it}$$
where  $I_{\tau}$  is a dummy variable equal to 1 if  $t = \tau$ , 0 otherwise (we only include  $T - 1$  dummies)
  - $\beta_{\tau} = E[Y_{it}|t = \tau] - E[Y_{it}|t = 1]$ : look for a break in the  $\beta$ 's after  $t^*$

## Adding a control group

- Even though adding more time periods alleviates some of the concerns, the interpretation of the  $\beta$ 's remains problematic
  - Has there been another shock in  $t^*$ ?
- One way to improve the simple difference method is to compare the before ( $T = 0$ ) and after ( $T = 1$ ) situation for
  - A treatment group ( $D = 1$ ) and a control group ( $D = 0$ )
- In  $T = 0$  no treatment and in period  $T = 1$  only one group is treated
  - Use the control group to correct for the influence of time (trend)
- Difference in differences (DD) estimator:

$$\beta^{DD} = E[Y_{it}|D_{it} = 1, T_{it} = 1] - E[Y_{it}|D_{it} = 1, T_{it} = 0] - (E[Y_{it}|D_{it} = 0, T_{it} = 1] - E[Y_{it}|D_{it} = 0, T_{it} = 0])$$

## Data example

- Let's assume that we also run our survey among 22 firms located in an adjacent country
- Country 2 does not introduce the carbon tax
  - Firms in country 1 are treated ( $treated=1$ )
  - Firms in country 2 are control ( $treated=0$ )
- For now we assume that we have just one survey observation before ( $after=0$ ) and one after ( $after=1$ )
- Intuitively: the DD estimator compares averages across four clusters (2x2 box)
  - This approach can be applied with repeated cross-sections or panel data

|    | country | year | treated | after | energy  | lnenergy |  |  |

## DD regression: notation

- Potential outcomes:  $Y_{1,igt}$  and  $Y_{0,igt}$   
where  $i$  are units of observations ( $1, \dots, N$ ),  $g$  are groups (0 if always untreated, and 1 if treated in  $t = 1$ ),  $t$  is time
- Assume homogeneous treatment effect:  $\beta = Y_{1,igt} - Y_{0,igt}$
- Denote conditional averages as follows:
  - $E[Y_{0,igt} | D_{it} = 0, T_{it} = 0] = \alpha$
  - $E[Y_{0,igt} | D_{it} = 0, T_{it} = 1] = \alpha + \lambda$
  - $E[Y_{0,igt} | D_{it} = 1, T_{it} = 0] = \alpha + \gamma$
  - $E[Y_{1,igt} | D_{it} = 1, T_{it} = 1] = \alpha + \gamma + \lambda + \beta^{DD}$
- Interpretation:  $\lambda$  is a period effect,  $\gamma$  is a group effect  
You can check that the DD estimator gives  $\beta^{DD}$

# DD: Causal effect identification

- Crucial identifying assumption: parallel trend
  - DD estimation identifies the impact of the intervention if treated and control units *would* follow the same trend *without* treatment
  - $E[Y_{0,igt}|D_{it} = 1, T_{it} = 1] - E[Y_{0,igt}|D_{it} = 1, T_{it} = 0] = E[Y_{0,igt}|D_{it} = 0, T_{it} = 1] - E[Y_{0,igt}|D_{it} = 0, T_{it} = 0]$
- With the notation above:

$$\begin{aligned}\beta^{DD} &= E[Y_{1,igt}|D_{it} = 1, T_{it} = 1] - E[Y_{0,igt}|D_{it} = 1, T_{it} = 0] - \\ &\quad (E[Y_{0,igt}|D_{it} = 0, T_{it} = 1] - E[Y_{0,igt}|D_{it} = 0, T_{it} = 0]) = \\ &= E[Y_{1,igt}|D_{it} = 1, T_{it} = 1] - E[Y_{0,igt}|D_{it} = 1, T_{it} = 0] \\ &\quad - (E[Y_{0,igt}|D_{it} = 1, T_{it} = 1] - E[Y_{0,igt}|D_{it} = 1, T_{it} = 0]) = \\ &= E[Y_{1,igt}|D_{it} = 1, T_{it} = 1] - E[Y_{0,igt}|D_{it} = 1, T_{it} = 1] = \beta\end{aligned}$$

# DD regression

- We are effectively comparing conditional means: We can just run a regression to estimate  $\beta^{DD}$
- With repeated cross-sections (i.e. not the same firms are surveyed in  $T = 0$  and  $T = 1$ ), we have:

$$Y_{igt} = \alpha + \lambda after_{igt} + \gamma treated_{igt} + \beta^{DD}(after_{igt} \cdot treated_{igt}) + e_{it}$$

- Under the parallel trend assumption,  $\beta^{DD}$  estimates the causal effect of the intervention  $\beta$ 
  - We use the evolution observed in the control group to construct a counterfactual outcome for the treated group

## DD with panel data

- Now consider a case where the same firms participate in the first and second waves of the survey
  - Repeated observations: panel dataset
- Instead of group fixed effect ( $treated=1$ ), we can introduce firm-level fixed effects
  - Recall: FEs control for all characteristics that are time-invariant
  - Same average as group-dummies, but more precise  $\beta^{DD}$

- We have:

$$Y_{igt} = \alpha + \sum_{j=1}^{N-1} \alpha_j I_j + \lambda after_{igt} + \beta^{DD}(after_{igt} \cdot treated_{igt}) + e_{it}$$

or simplifying notation:

$$Y_{igt} = \alpha_i + \lambda after_{igt} + \beta^{DD}(after_{igt} \cdot treated_{igt}) + e_{it}$$

- In Stata, `xtset` your data and use `xtreg` with the option `fe`
  - Adjust standard errors for clusters (`cluster(firms)`)

## DD with more than two periods

- Consider again a case where we observe firms four years before the interventions and four years after
- Use period fixed effects to flexibly measure how the outcome evolves among control units
  - Recall: time FEs capture all phenomena that affect all units at a given point in time (macro shocks)

- Regression equation:

$$Y_{igt} = \alpha_i + \sum_{\tau=2}^T \lambda_{\tau} I_{\tau} + \beta^{DD}(\text{after}_{igt} \cdot \text{treated}_{igt}) + e_{it}$$

or simplifying notation:

$$Y_{igt} = \alpha_i + \lambda_t + \beta^{DD}(\text{after}_{igt} \cdot \text{treated}_{igt}) + e_{it}$$

- Identifying dynamic effects: instead of an average impact we can estimate per-period impact  $\beta_{\tau}^{DD}$

$$Y_{igt} = \alpha_i + \lambda_t + \sum_{\tau=t^*}^T \beta_{\tau}^{DD}(I_{\tau} \cdot \text{treated}_{igt}) + e_{it}$$

# Parallel trends?

- The assumption of parallel trends cannot be directly tested
  - We would need to observe both potential outcomes
- However, we should document whether the parallel trend assumption is plausible before treatment
- Two suggestions to provide evidence about *pre-treatment* trends
  1. Plot average outcomes for treated and control units over time
  2. Placebo test: introduce DD estimates in all years before  $t^* - 2$  and show that  $\delta_{\tau}^{DD}$  estimates are not statistically significant
$$Y_{igt} = \alpha_i + \lambda_t + \sum_{\tau=1}^{t^*-2} \delta_{\tau}^{DD} (I_{\tau} \cdot treated_{igt}) + \beta^{DD} (after_{igt} \cdot treated_{igt}) + e_{it}$$
- Note functional form dependence: the parallel trend may hold for logs but not for levels (and conversely)
  - Can select preferred functional form in light of pre-treatment trends

## DD: Remarks and pitfalls

- In this case the results suggests that pre-treatment trends are not parallel
  - Try linear specification instead
- Alternatively, control for firm-level time-varying characteristics
  - Avoid bad controls: only variable that are not affected by the treatment can be included
- Heterogeneous treatment effect: Exploit within-treated variation to quantify differences in  $\beta^{DD}$  across clusters
  - Interact  $after_{igt} \cdot treated_{igt}$  with pre-treatment variables for treated units
- Other pitfall: there should be no spillover across treatment and control groups (e.g. trade among countries?)

## Comparative case study: Synthetic control

- In some settings only one or a very small number of units are treated
  - Finding a control group with parallel trend is likely to fail
- Synthetic control (Abadie and Gardeazabal, 2003): DD-style estimator for “case studies”
  - Growing in popularity: 2000+ citations on Google scholar
- Intuition: construct a weighted average of control units to match pre-treatment trajectory for the treated unit
  - Then compare the post-treatment trajectory for the treated unit and the synthetic counterpart

# Synthetic control: Notation

- Outcome variable for treated unit:  $Y_t$ 
  - Outcome for the synthetic unit:  
 $Y_t^{SCM} = \sum_i \omega_i Y_{it}$   
where  $i$  is set of untreated units (the “donor pool”) and  $\omega_i$  is the weight attributed to each unit  $i$
- Weights  $\omega_i$  minimize the distance between  $Y_t$  and  $Y_t^{SCM}$  before  $t^*$ :  
$$\min_{\omega_i} \sum_{t=0}^{t^*-1} (Y_t - \sum_i \omega_i Y_{it})^2$$
  
s.t.  $\sum_i \omega_i = 1, \omega_i \geq 0$
- Treatment effect:  $\beta_t = Y_t - Y_t^{SCM}$

# Synthetic control: Example

- Sweden implemented a carbon tax in 1991
  - Starting at US\$30/tCO<sub>2</sub> up to US\$132 in 2019
  - Mainly affect transportation sector (exceptions for industries)
  - What is the control group?
- Andersson (AEJ: EconPolicy, 2019) constructs a “synthetic” Sweden
  - Donor pool: all OECD countries
  - Compute weights given to each OECD country
  - Matching period: 1960 to 1990
- The impact of the 1990 carbon tax: compare CO<sub>2</sub> emissions in Sweden against its synthetic counterfactual

TABLE 2—COUNTRY WEIGHTS IN SYNTHETIC SWEDEN

| Country   | Weight | Country       | Weight |
|-----------|--------|---------------|--------|
| Australia | 0.001  | Japan         | 0      |
| Belgium   | 0.195  | New Zealand   | 0.177  |
| Canada    | 0      | Poland        | 0.001  |
| Denmark   | 0.384  | Portugal      | 0      |
| France    | 0      | Spain         | 0      |
| Greece    | 0.090  | Switzerland   | 0.061  |
| Iceland   | 0.001  | United States | 0.088  |

Note: With the synthetic control method, extrapolation is not allowed so all weights are between  $0 \leq w_j \leq 1$  and  $\sum w_j = 1$ .

# Implementation in Stata

- Synthetic control in Stata: user written command “synth”
  - Written for the paper Abadie et al. (JASA, 2010), also available for R (and Matlab)
- Implementation: Consider simulated data on energy use observed over 8 years:
  - 1 country imposes a carbon tax in period 5 and later
  - 5 countries have no tax and are included in the donor pool
- Our objective is to combine the 5 countries into a synthetic control
  - First we need to install the package and declare group/time dimensions

# Synthetic control: Placebo experiments

Make a mistake to check reliability

- One may wonder if these results are just derived “by chance”
  - Placebo experiments: try to convince the reader that the treatment effect is not spurious
  - Abadie: Akin to making a mistake in the estimation code!
- 1. In-time placebo: Shift the treatment to a prior time period

We would want to see the treatment effect only start with a delay

Check and look for a good fit
- 2. In-space placebo: Re-assign the treatment to each unit in the donor pool, and re-run the algorithm
  - Use only non-treated units
  - Allows a form of inference: p-values as the fraction of donor pool units with a treatment effect that is larger than that of the treated unit

FIGURE 6. PLACEBO IN-TIME TESTS

*Notes:* In panel A, the placebo tax is introduced in 1980, ten years prior to the actual policy changes. In panel B, the placebo tax is introduced in 1970.

## Wrapping up

- DD estimation: Illustrates how variability in treatment assignment identifies the treatment effect in a panel FE model
  - Use units in the control group to estimate a counterfactual trajectory
- Need to document whether the parallel trend assumption is plausible *before* the treatment
- With synthetic control, we impose both level and trend equality prior to treatment
  - Downside: this is only a case study: can we generalize?
